

# Genetic Unit Commitment Model In A Deregulated Power Energy Environment

C. A. Baloi, J. A. Belward and M. Bulmer

University of Queensland, Australia ([s007678@student.uq.edu.au](mailto:s007678@student.uq.edu.au))

**Abstract:** In the last decade, Australia had applied a large program of privatisation in many sectors of the economy. As a result, the power industry has been deregulated and undergone partial privatisation, creating new specific issues. In present, the bid price has a crucial role in the unit commitment problem. This paper describes a genetic algorithm approach which solves the unit commitment problem for two interconnected regions of the National Electricity Market. This ‘biological’ algorithm is an alternative to classical optimisation methods and is applied to optimise the scheduling of units, including the economic dispatch, in Queensland and New South Wales. A comparison between the results of this model and a sequential model applied to the same problem is presented.

**Keywords:** *Unit commitment; Genetic algorithms; Bid price; Electricity*

## 1. INTRODUCTION

The aim of this paper is to determine if a model based on genetic algorithms can find an optimal or near optimal solution for a large multi-area unit commitment problem (two regions) in a deregulated energy market.

The objective of the *multi-area unit commitment problem* is to find an optimal scheduling of units, including the allocation of the generation quantities of each unit, in order to minimize the total cost of dispatched electricity for all regions, during a time horizon, subject to a set of constraints.

Radcliffe (1992) and Michalewicz (1994) revealed statements concerning the suitability of genetic algorithms to solve a large range of unconstrained or constrained problems.

Smith (1994) shown that “from the multitude of examples of genetic algorithms applied to different optimisation problems, there is a small number of examples published of where they are successfully applied to practical applications”.

Genetic algorithms replace totally classical optimisation techniques and it is considered that this intelligent technique can solve suitable difficult problems in the new power electricity environment.

The power of a genetic algorithm arises from the concept of ‘implicit parallelism’ (Holland 1975, Goldberg 1989). Holland (1975) defined a schema as a similarity template describing a subset of structures with similarities of certain gene positions. During the search, the similarities

between structures conduct the algorithm to better and better solutions.

A candidate solution is a chromosome whose length is the product of the number of units and the number of trading periods. In conformity with the biological terminology, a solution is called *chromosome* and contains a sequence of *genes*. All the chromosomes create a population.

The fundamental optimisation process encompasses a combination of chromosomes which produces better and better chromosomes (solutions) with almost each generation during the search algorithm.

In this paper, the unit commitment problem is solved in a deregulated environment and the units, scheduled based on the *bid price*, can dispatch any quantity of electricity starting with the minimum quantity up to their full capacity instead to be simple on (at full capacity) or off.

## 2. GENETIC ALGORITHMS METHOD

A genetic algorithm is a stochastic search technique based on natural inheritance and the Darwinian ‘survival of the fittest’ law (Goldberg 1989). Since the nature is in a permanent process of adaptation, genetic algorithms appear to be suitable to solve optimisation applications in real life.

On brief, a genetic algorithm starts with a ‘randomly’ generated initial population of feasible solutions. Each solution is evaluated and selected according to its fitness. Genetic operators are applied to the population and, in most of the cases, a new generation of better solutions is

obtained. The algorithm is performed until an optimal or near optimal solution is obtained.

In order to solve a problem using this method, a series of components must be defined:

- A coding for parameters;
- A way to create an initial population of feasible solutions;
- A fitness function;
- A set with the probabilities of genetic operators and population size.

The values of the parameters used by a genetic algorithm are not universally suitable for any problem. These values are different, being problem dependent and there is a complex task to find them. Thus, for any type of problem, a series of experiments are recommended in order to find the most appropriate parameter values.

### 3. TWO REGIONS GENETIC UNIT COMMITMENT MODEL (GA\_2\_51)

#### 3.1. Introduction

The model uses both decimal and binary representation. Each generator is represented by two strings of nine genes. The initial population is generated by randomly creating 2 decimal numbers between 0 and 511 for each generator. Each of these numbers can be represented binary by a string of nine genes.

After the first generation is randomly created, the total cost, quantity and fitness are evaluated. The quantity allocated to each generator is:

$$Q_i = \text{Minimum generation} + \Delta_i (X_i + 1),$$

where  $X_i$  is the value of the random numbers transformed in a decimal number and  $\Delta_i$  is the interval width.

The price corresponding to the allocated quantity is calculated taken into consideration each of the band of the scheduled offers.

The objective is to schedule the units in such a way that the total demand is attained and the interconnector limits are met and the total sum paid to the generators is minimal. For each member of the population, the deviation from the load is  $\Phi_i$ , that is the difference between the total generation of the units and total demand for the two regions.

For the total cost function (TCF), it is necessary to impose penalties for not meeting the demand and for exceeding each interconnector limit. The penalty for exceeding the limit of the interconnector from region 1 to 2 is denoted by

$\text{Int}_{12\_Penalty}$  and for the reverse direction  $\text{Int}_{21\_Penalty}$ .

The penalty for exceeding the limit of interconnector from region  $k$  to region  $j$   $\text{Int}_{kj\_Penalty}$ ,  $k = 1$  and  $j = 2$  or  $k = 2$  and  $j = 1$ , applies only when the generation of region  $k$  exceeds the sum of the demand for region  $k$  and interconnector limit from region  $k$  to region  $j$ . In this case the penalty is applied to the exceeding amount. Therefore, the total cost function (TCF) is calculated as follows:

$$\begin{aligned} \text{TCF} = & \text{Total gen. cost} + D \text{ Penalty} * |\Phi_i| + \\ & \text{Int}_{12\_Penalty} * \text{Max}(0, \text{Total gen. region 1} - \\ & D \text{ region 1} - \text{Interconnector limit}_{12}) + \\ & \text{Int}_{21\_Penalty} * \text{Max}(0, \text{Total gen. region 2} - \\ & D \text{ region 2} - \text{Interconnector limit}_{21}) \end{aligned}$$

The fitness function was defined as:

$$\text{Fitness} = 1/\text{TCF} * 1,000,000.$$

After the fitness is evaluated for each member of the initial population, the population is sorted descending function of the individual fitness.

Roulette wheel was employed as a mean of selection. Each member has assigned an equal sector between 0 and 1, such that the sum of all the sectors is 1.

Each string is assigned a random number between 0 and 1 and function of its sector and this number, the string is selected for participating in the crossover. The crossover and mutation rates are set at the beginning of the modelling.

The new population is translated back into decimal notation and the process of calculating all the statistics starts again.

The model was developed in exclusivity on the genetic algorithm method. It was applied on a deregulated two-region interconnected power system in the Australian national market. Queensland (region 1) contains 27 units and NSW (region 2) has 24 units.

The demand for period 1 of 1 July 1999 was 2980 MW for Queensland and 6770 MW for NSW. Each unit has 10 price bid offers and 10 quantity bids (for each half-hourly period). The interconnector limits are as follows:

- From Region 1 to 2 is 800 MW;
- From Region 2 to 1 is 600 MW.

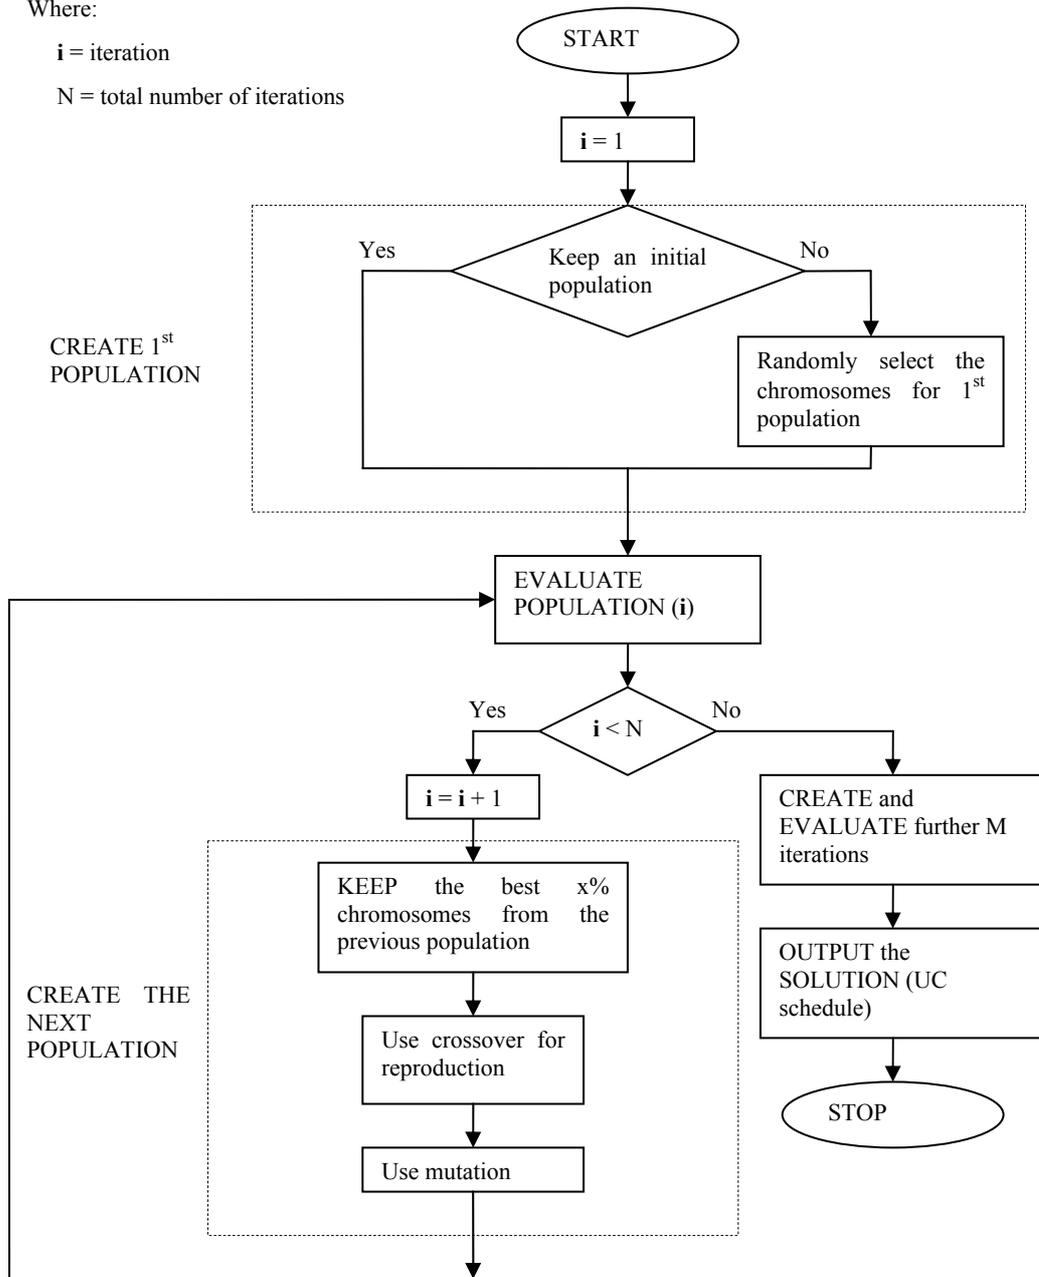

The code is written in Visual Basic for Applications with an Excel interface. The algorithm stops when the number of iterations set has been reached. The genetic flow chart is shown in **Table 1**.

**Table 1** Flow chart of the genetic algorithm model GA\_2\_51

Where:

$i$  = iteration

$N$  = total number of iterations

GA\_2\_51 uses as an initial feasible solution the chromosome which has all the values equal to zero, in order to have selected only the minimum generation given by the baseload units. GA\_2\_51 was run 5 times and parameters for each trial were:

- Mutation percent = 10%
- Crossover percent = 95%
- Number of iterations = 150
- Penalty for not meeting demand = \$100/MWh

- Penalty for exceeding the interconnector limit = \$100/MWh
- Elitism – keep the best chromosome.

A sequential model (SQM\_2\_51) is applied to the same unit commitment problem and the results between the two models are compared. The sequential model is exclusively developed using the sequential method. Based on *bid price*, this model employs a bidding procedure to sequentially identify the next most economic unit to be committed.

Both models were run for one period and all the units are not operational.

### 3.2. Results and analysis

The SQM\_2\_51 find the solution in 0.12 seconds:

- Total cost of electricity dispatched is \$25,382.35;
- Pool price for Queensland is \$3.80/MWh and \$7.67/MWh in NSW;
- Queensland generated 3135 MW and exported 155 MW to NSW;
- NSW generated the remaining 6615 MW.

The computational time for GA model was 2.5 hours per trial. The average total cost solution of the 5 trials was \$27,962 and the minimum attained in Trial 1 was \$26,794 compared with

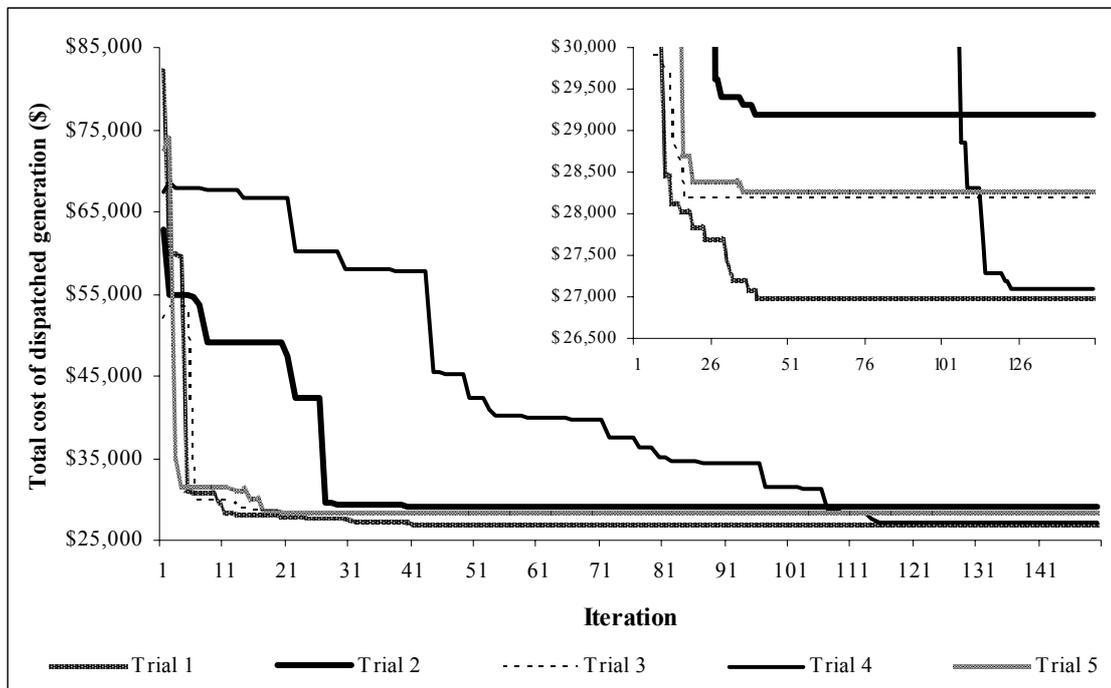

SQM\_2\_51 solution of \$25,382 (at minimum a variation of 6.27%).

The average total cost solution of the 5 trials was \$27,962 and the minimum attained in Trial 1 was \$26,794 compared with SQM\_2\_51 solution of \$25,382 (at minimum a variation of 6.27%).

Trial 1 has the pool price for Queensland of \$3.80/MWh (same as SQM\_2\_51) and \$9.82/MWh for NSW. The interconnector transfer between 44 MW to 442 MW. The statistic results are presented in **Table 2**, total cost of dispatch in **Figure 1**, dispatch schedules are shown in **Table 3** and best fitness in **Figure 2**.

**Table 2** Statistics results for GA\_2\_51 and SQM\_2\_51

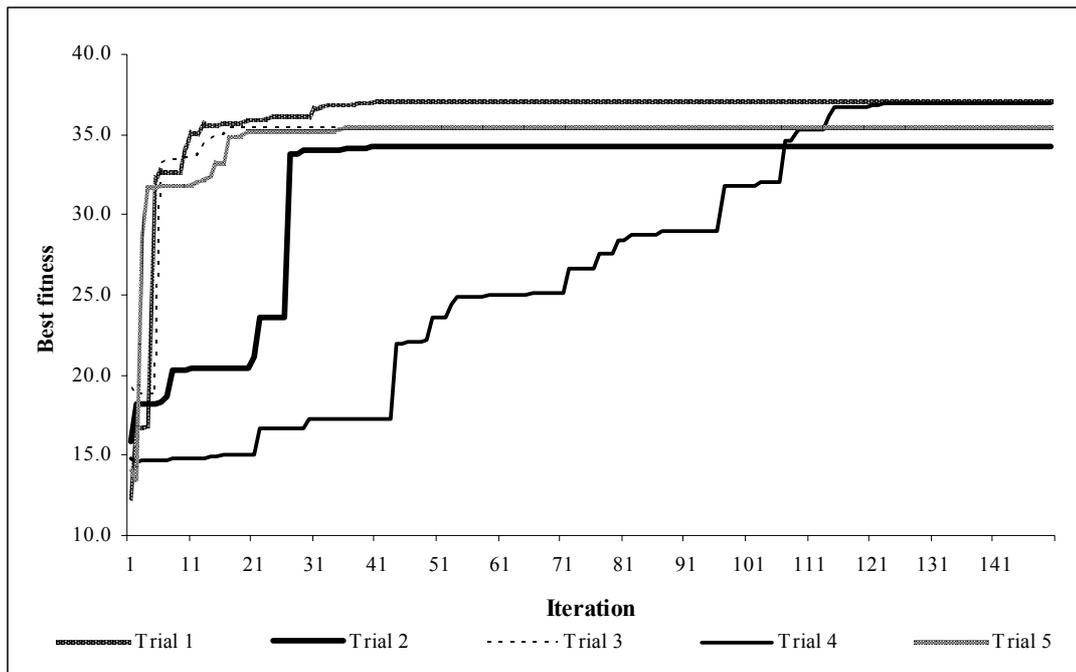

| Trial Number | Total Cost (\$) | NSW Pool Price (\$/MWh) | Qld Pool Price (\$/MWh) | NSW Generation (MW) | Qld Generation (MW) | Interconnector transfer (MW) |
|--------------|-----------------|-------------------------|-------------------------|---------------------|---------------------|------------------------------|
| 1            | \$26,974        | \$9.82                  | \$3.80                  | 6726                | 3024                | 44                           |
| 2            | \$29,180        | \$13.57                 | \$13.79                 | 6509                | 3241                | 261                          |

#### 4. CONCLUSION

Recently, noticeable progress has been made towards the application of genetic algorithms in solving some problems of the power energy industry.

This 'biological' algorithm approach, as an alternative to classical optimisation methods, solves the unit commitment problem for two interconnected regions of the national market, based on *bid price*.

Thus, the model is applied on a large scale power system with 51 generation units which are competing in a deregulated environment and provides good schedules of units including the economic dispatch. The units can dispatch any quantity of electricity starting with the minimum quantity up to their full capacity.

The genetic algorithm model found in all cases near optimal solutions and the application of this technique to power energy industry is promising very good results in the future.

Based on the theoretical foundations of genetic algorithms and taken into consideration the computer equipment used in this modelling, the computational time, as expected, is very high. This limiting factor can be addressed using powerful workstations with large memory and many microprocessors, currently available at reasonable price.

In comparison with the genetic approach, sequential model proved to be very efficient, given the 'optimal' solution in real time (0.12 seconds).
